

# Abstract

## Aim

Testing the relationship between change in community-level abundance and community function (biomass and energy use), as mediated by change in the individual size distribution.

This is the first macroecological-scale study of the interrelated dynamics of ISDs, abundance, and function for terrestrial animal communities.

## Location

North America, north of Mexico.

## Time period

1988-2018

## Major taxa studied

Breeding birds

## Methods

We simulated ISDs for the time periods 1988-1992 and 2014-2018 for 528 routes in the Breeding Bird Survey. We evaluated 1) the extent of change in the ISDs from the beginning to the end time periods; 2) the change in total biomass and total energy use over this time span; 3) the extent to which the observed changes in biomass and energy use reflect changes in numerical *abundance* vs. change in the ISD.

## Results

Nearly all ISDs have changed detectably over time, but in most instances this does not result in a decoupling between biomass/energy use and numerical abundance. However, in a substantial minority of communities - 30% of routes overall for biomass, and 14% overall for energy use - directional shifts in the ISD result in a decoupling. In 80% of instances of decoupling, the deviation is towards an increase in body size/per capita metabolic rate, resulting in a less negative change in function than the change driven by numerical abundance.

## Main conclusions

Terrestrial animal ISDs are dynamic; these dynamics have consequences for the scaling of abundance and function; and this study provides tools and motivation for examining these dynamics!

## Introduction/Framing

Understanding the interrelated dynamics of size- and -abundance based dimensions of biodiversity is key to understanding biodiversity change in the Anthropocene. Total abundance - i.e. the total number of individual organisms present in a system - and size-based currencies, such as the total biomass or total metabolic flux (“energy use”) of a system, are intertwined, but nonequivalent, measures of biological function. Abundance is more closely tied to species-level population dynamics, while size-based metrics more directly reflect assemblage-level resource use and contributions to materials fluxes at the broader ecosystem scale (Morlon et al. 2009, Dornelas et al. 2011, Connolly et al. 2005, White et al. 2007). While these currencies are naturally linked (Morlon et al. 2009, Henderson and Magurran 2010), changes in size composition can decouple the dynamics of one currency from another (Ernest et al. 2009, Dornelas et al. 2011, White et al. 2004, 2007, Yen et al. 2017). This can mean that intuition from one currency may be misleading about others; a trend in numerical abundance might mask something else going on with biomass (White et al. 2004). Changes in size composition strong enough to decouple currencies may be symptomatic of important changes in ecosystem status- e.g. abundance-biomass comparison curves (Petchey and Belgrano 2010); size-biased extinctions (Young et al. 2016, Smith et al. 2018). This underscores the need to understand how these dynamics are playing out in the Anthropocene (Fisher et al. 2010).

At the **community scale**, changes in the relationship between size and abundance tells us about important functional shifts. This is the scale at which ecological processes (i.e. compensatory dynamics, niche tracking, functional replacement) come into play - in contrast to population or global trends (White et al. 2007, Dornelas et al. 2014, McGill et al. 2015). To the extent that size is a proxy for other functional traits, changes or consistency in the community-level size structure (individual size distribution, ISD) over time may reflect processes related to niche structure (White et al. 2007, Petchey and Belgrano 2010). Strong size shifts can decouple the relationship between abundance and biomass. In aquatic systems, such changes in the scaling between abundance and biomass often signal ecosystem degradation (Kerr and Dickie 1AD, Warwick and Clarke 1994 and refs therein, Petchey and Belgrano 2010). Compensatory shifts in the size structure can buffer community function (in terms of biomass or energy use) against changes in abundance (Ernest et al. 2009, White et al. 2004, Terry and Rowe 2015). Consistency in the size structure may maintain the relationship between size- and -abundance based currencies, even as species composition, total abundance, and total biomass/total energy use fluctuate over time, which can reflect consistency in the niche structure over time (Holling 1992).

It is important to improve our understanding of these dynamics for terrestrial animal communities in particular. In contrast to terrestrial trees and aquatic systems (Kerr and Dickie 1AD, White et al. 2007), how the relationship between size and abundance changes over time, and the consequences of these changes for ecosystem-level properties, remain relatively unknown for terrestrial animals (but see White et al. (2004)). Terrestrial animal communities exhibit size structure (Thibault et al. 2011, Ernest 2005), and case studies have demonstrated that size shifts can either decouple N from E for terrestrial animals (White et al. 2004, Yen et al. 2017), but not always (Hernández et al. 2011). Establishing generalities in these dynamics is especially pertinent in the Anthropocene, as these communities are experiencing extensive and potentially size-structured change, with implications at community, ecosystem, and global scales (Young et al. 2016, Schmitz et al. 2018).

Macroecological-scale synthesis on the interrelated dynamics of the ISD, total abundance, and community function for terrestrial animals has been constrained by 1) a lack of community-level size and abundance timeseries data for these systems (Thibault et al. 2011, White et al. 2007), and 2) appropriate statistical methods for relating change in the size structure to changes in abundance and function (Thibault et al. 2011, Yen et al. 2017). In contrast to aquatic and forest systems, most long-term surveys of animal communities do not collect data on individuals’ *sizes* across a full community (with the exception of small mammal studies, which have made major contributions to our understanding of the dynamics of size, abundance, and function for these systems; (White et al. 2004, Ernest 2005, Hernández et al. 2011, Kelt et al. 2015)). Global, continental, or population-wide studies capture different phenomena [White et al. (2007); this is a nod to a few studies looking at the size structure *across Britain* or something]. The ISDs for terrestrial animals, and specifically for determinate growing taxa (e.g. mammals, birds), are often complex, multimodal distributions

(Holling 1992, Thibault et al. 2011, Ernest 2005, Yen et al. 2017), and less statistically tractable than the power-law ISDs found in aquatic and tree systems [Kerr and Dickie (1AD); White et al. (2007); more]. Quantifying change in the size structure, and relating this to change in community-wide abundance and function, is not as straightforward as computing and comparing slopes. As a result, we do not have a general understanding of either 1) how these ISDs behave over time or 2) the extent to which changes in the ISD decouple the community-level dynamics of abundance, biomass, and energy use in these systems.

Here, we begin to address this gap by exploring how temporal changes in species composition and the size spectrum modulate the relationship between total abundance, energy, and biomass for communities of North American breeding birds. We used allometric scaling to estimate community size and abundance data for the North American Breeding Bird Survey, and evaluated how changes in total abundance, biomass, and energy use have co-varied from 1988-2018. Specifically, we examined: 1) How often do these currencies change together vs. have decoupled dynamics?; 2) What are the dominant directions and magnitudes of the overall change and any decoupling between the currencies?; 3) To what extent do changes in the ISD translate into decoupling between abundance and function?

# Methods

## Bird abundance data

We used data from the Breeding Bird Survey (Sauer et al. 2013) to compare community attributes along each route between the 5-year periods from 1988-1992 and 2014-2018. We take the route to be the “community” scale [Thibault et al. (2011); others]. BBS (BBS methods background). We filtered the data to remove taxa that are poorly sampled through these methods, following (literally everyone). We accessed the data, and performed this preliminary cleaning and filtering, using the R package `MATSS` (Ye et al. 2020).

We used a discrete time-period comparison (as opposed to continuous-time over the full timeseries) to simplify comparisons between temporal turnover in the size structure - which are complex, multidimensional distributions - and changes in community-wide total abundance, biomass, and energy use. We acknowledge that a continuous-time perspective may be better equipped to detect nonlinear dynamics (Macgregor et al. 2019) and account for artefacts related to the selected beginning and ending dates (Cusser et al. 2020, Bahlai et al. 2021). Developing continuous-time methods for analyzing community distributions such as multimodal size spectra is an important and ongoing area of methodological development (e.g. Yen et al. (2017)).

We used 5-year periods to account for sampling accumulation effects in characterizing the bird community in each time period (White 2004). We used the same begin and end dates for all routes in the analysis so as to have a consistent window. We explored the number of routes in the dataset with complete sampling coverage for two five-year “begin” and “end” periods with start dates ranging from 1970 to 1990 and end dates ranging from 2000 to 2018, and selected beginning and ending dates of 1988 and 2018 so as to obtain a large number of routes from diverse bird conservation regions, and span a relatively long window of time (could ref Cusser et al. (2020) there). This yielded 528 routes.

## Estimated size data

BBS contains abundances for all species along a route in each year, but does not include measurements of individual body size. We generated body size estimates for individual birds assuming that intraspecific size distributions are normally distributed around a species’ mean body size (following Thibault et al. (2011)). Using records of species’ mean and standard deviation body sizes from (???), we drew individuals’ body sizes from the appropriate normal distributions. For species for which there was not a standard deviation recorded in (???) (185 species affected, of 421 total), we estimated the standard deviation based on an allometric scaling relationship between mean and standard deviation in body mass ( $\log(\text{variance}) = -5.273 + (\log(\text{mass}) * 1.995)$ ); model  $R^2$  .86; see also Thibault et al. (2011)). For species with multiple records in (???), we used the mean mean and standard deviation body sizes across all records (averaging across sexes, subspecies, and records from different locations). We performed this averaging after estimating any missing standard deviation measurements. For each individual bird observed, we estimated metabolic rate as  $10.5 * (\text{mass}^{.713})$  (???, ???, Fristoe 2015). For each route in a given year, we compute total energy use, total biomass, and total abundance by summing over all individuals observed on that route in that year. This method does not incorporate intraspecific variation in body size across geographies or over time (???, Gardner et al. 2011). However, it makes it possible to conduct macroecological studies of avian size distributions at a spatial and temporal scale that would otherwise be impossible (Thibault et al. 2011).

## Comparing ISDs over time

For each route, we used two approaches to test whether the ISD for 1988-1992 is significantly different from the one for 2014-2018. First, we used a Kolmogorov-Smirnov test on the vector of masses for the beginning and end time periods. Second, we performed bootstrap resampling to test whether the observed degree of dissimilarity between the two time periods exceeded that which would be expected if the probability of an individual being a particular size did not depend on which time period it was observed in (I believe

following Ernest (2005)). From the pool of all individuals observed in both timeperiods, we re-assigned individuals to each time period at random and without replacement, and computed the Kolmogorov-Smirnov test statistic  $D$  comparing the resulting vectors of masses for each time period. We repeated this 500 times, and calculated the percentile score and standardized effect size (SES) of Kolmogorov-Smirnov  $D$  for the *observed* ISDs compared to the distribution of  $D$ s from the bootstrap samples. Percentile scores  $> 95$  and  $SES > 2$  correspond to an observed pair of ISDs significantly more dissimilar than the bootstrap samples.

For an intuitive measure of the *magnitude* of change in the ISD over time, we compute an overlap measure (see Read et al. (2018) for this measure applied to species-level body size distributions). We characterize the ISD as a smooth function by fitting a Gaussian mixture model (to logarithm of mass, up to 15 Gaussians, select best using BIC, all following Thibault et al. (2011)). We evaluate the density function of the GMM at points for a size range from  $0\text{-exp}(15)$ , which covers the range of sizes in this dataset with ample padding on each side. We rescale the density function so the total area under the ISD is 1. We calculate the overlap between two ISDs as the sum of the minimum density at each evaluation point. This ranges from 0 (no overlap) to 1 (complete overlap) (Read et al. 2018).

Here is an example of a real set of “begin” (red) and “end” (blue) ISDs, and the results of a single bootstrap shuffle. For this site (`dat$metadata$location$routename`, `dat$metadata$location$regionname`), the KS test p value is `round(isd_comparison$actual_p[1], 4)`. The observed test statistic has a percentile of `round(isd_comparison$d_percentile[1], 2)` and SES of `round(isd_comparison$d_ses[1], 2)` compared to 500 bootstraps. The observed ISDs have an overlap of `round(isd_comparison$overlap, 2)`.

## Decoupling of dynamics in total abundance, biomass, and energy use over time

### Sims

To test whether change in biomass or energy use deviates from the change in abundance, we can’t just compare the slopes for total energy, total biomass, and total abundance to each other. This is because the three different currencies are on radically different scales of measurement. We also can’t rescale using the usual methods (e.g. scale to mean 0/sd 1, sqrt transform Dornelas et al. (2014); Gotelli et al. (2017)) because these destroy information about the range of variability within a single currency. Instead, we test whether the observed change in biomass or energy use differs from the change that we would expect given observed changes in community-wide abundance, but with *no change* in the ISD from beginning to end.

We simulate change in total energy and total biomass under “no change in ISD” and “observed change in ISD” scenarios. We use the GMM smooth procedure described above to characterize a “sampling GMM” for each time period. The “sampling GMM” is a probability density function with the probability of observing an individual of a given mass across the spectrum of possible masses. Sampling `$mass` with probability `$density` is a random number generator for sizes. We then *re draw* individuals for each year under different scenarios. First, we draw individuals for each year using the actual ISD for that time period (so the “begin” ISD for 1988-1992 and the “end” ISD for 2014-2018). Second, we draw individuals for each year, but using the “begin” ISD for all years, to estimate community properties if the ISD had not changed from beginning to end. We compute the total energy use and total biomass for each year under each scenario.

Note that we pool individuals within a time period to create the ISD, to smooth out species accumulation, but we draw individuals and compute total energy and biomass year-by-year, instead of pooling individuals over the whole time period, to capture interannual, intratimeperiod variation in total abundance (which propagates to total energy use and total biomass).

Here, the “abundance” line (red) reflects change in total biomass expected due only to changes in abundance. The “currency” line reflects change in total biomass due to change in abundance *and* observed change in the size structure. Deviations in slope between the red and blue lines reflect change driven by the ISD. Note that the lines here are crude linear model smooths and not really suitable for inference, just visualization.

## Testing change

We use Bayesian linear models to test whether change in the ISD decouples the dynamics of total biomass/total energy use from that which would be expected due to change in abundance.

We evaluate change at the route level, because we care most about the decoupling of slopes for “currency” and “abundance” at the route level.

For each currency for each route, we fit 3 models:

1. `total_biomass ~ timeperiod * scenario`: I call this one “full”; this model has a slope for abundance, and an offset resulting in a *different* slope for currency
2. `total_biomass ~ timeperiod`: I call this one “nosource”; this one has a slope for abundance but not a different slope for currency
3. `total_biomass ~ 1`: Intercept-only model, no change over time.

We fit as Gaussians with default priors, run for 8000 iterations. We used LOO-crossvalidation (as implemented in `rstanarm::loo`) to select the best-fitting model as the simplest model with an ELPD within 1 SE of the best-fitting model, using `relloo` to correct for outliers.

If the best-fitting model does not include the scenario term (i.e. “currency” separate from “abundance”), it means that the change in the ISD does not ~significantly decouple the dynamics of total energy/biomass from that which is driven by changes in abundance. If there is no **timeperiod** term, it means that there’s not a ~significant change begin-end.

We fit these models for **total\_biomass** and **total\_energy** for all routes. For each currency, we tallied: 1. How often the best model includes the “source” term (meaning there’s a decoupling); 2. how often there’s a timeperiod but no source term (meaning there’s change over time, but that biomass/energy use do not diverge from abundance); 3. how often there’s no timeperiod term (meaning no ~significant change begin to end).

For the example site we’ve been working with, here are the winning models. Both biomass and energy select the “full” model, meaning there’s a decoupling between the size-based currencies and just abundance.

For models with slope and/or offset terms, we extracted estimates for the slope for abundance, and the offset for currency, to examine the magnitude and direction of change and decoupling. We tallied how often the abundance slope was positive or negative (how often the 95% CI for the timeperiod term is  $>/< 0$ ) and how often the offset for currency is positive or negative (how often the 95% CI for the timeperiod:source term is  $>/< 0$ ). Positive offsets mean that the change in biomass/energy use is less negative than change in abundance; negative offsets mean that the currency is more negative.

For the example route we’ve been working through, here are the parameter estimates for the slope and offset (means and 95% CIs). For both energy and biomass, the abundance-driven trajectory is an increase, although biomass gets closer to over 0. For both, the currency-driven offset is also an increase, meaning that the change in the ISD caused biomass to increase more than we expect it to just because of the increase in abundance.

## Relating change in the ISD to decoupling

The ISD may change without resulting in a detectable decoupling of the dynamics of biomass/energy use and abundance at the whole-system level, if the change in the ISD is relatively ~balanced above and below the mean body size. We tested whether communities with a decoupling showed greater change in the ISD than systems that did not, using a linear model of the form `isd_overlap ~ winning_model_type` using both the winning models for energy use and for biomass. We also tested the extent to which change in mean body size was linked to change in the ISD using a linear model of the form `absolute_log_ratio_mean_size ~ isd_overlap`.

## Core-transient

Because core and transient species may have different dynamics, we ran this pipeline on whole communities, and using just core species (those present in  $\geq 2/3$  of timesteps).

## Highly-sampled BCRs

I subsampled the 528 routes to get a maximum of 10 routes per bird conservation region, so that the highly-sampled BCRs don't dominate aggregate analyses (Thibault et al. 2011). That yields 238 routes total. Results are the same; I haven't included them in this document.

# Results

## Overview

Here are the key points - more detailed plots and tables follow:

- The ISD is almost always “different” from beginning to end. The question is, what are the consequences of this change?
- About 1/3 of routes do not find a significant change in abundance, energy use, or biomass beginning to end.
- For routes with change in abundance from beginning to end, the majority of the time this is a **decrease in total abundance**. (70% of changes in abundance are a decrease).
- About 1/3 of the time (for biomass) and 1/6 of the time (for energy use) change in the ISD drives the currency change away from the change driven by just abundance. When this happens, **75-80% of the time** the change for the currency is less negative than the change in abundance (corresponding crudely to an increase in mean body size/per capita metabolic rate).
- There is not a strong relationship between the magnitude of change in the ISD overall and a) whether a route has a slope or decoupling or b) shifts in mean body size.
- If we restrict to only core species, 1) we see decoupling less frequently; 2) for core species, the decoupling due to change in the ISD is evenly distributed between decreases and increases (whereas, if we include all species, it is skewed towards increases in body size/metabolic rate resulting in less negative slopes for biomass/energy use than for abundance). Changes in abundance remain predominately decreases.

## Change in the ISD begin-to-end

### “Significance”

In `sum(all_comps$actual_p < .05)` of `nrow(all_comps)` routes, the KS-test finds a significant difference in the raw ISDs begin-to-end. In `sum(all_comps$d_percentile > .95)` of `nrow(all_comps)`, the percentile score of the KS-test statistic (relative to the bootstrap model) is greater than .95. In `sum(all_comps$d_ses > 2)` of `nrow(all_comps)`, the SES > 2. We proceed as though the “begin” and “end” ISDs are always “significantly” different, and investigate the magnitude and consequences of these differences.

### Magnitude

For most sites, these significant differences translate into about 80% overlap/20% change in the distribution of density under the ISD - similar to the degree of change in the example shown above.

## Change in abundance and function

### Model tallies

For  $\text{round}(100 \times \text{mean}(!\text{grepl}(\text{"notime"}, \text{actual\_winners}[\text{ which}(\text{actual\_winners}\$currency == \text{"energy"}), ]\$model)))$  percent (for energy use) and  $\text{round}(100 \times \text{mean}(!\text{grepl}(\text{"notime"}, \text{actual\_winners}[\text{ which}(\text{actual\_winners}\$currency == \text{"biomass"}), ]\$model)))$  percent (for biomass) of routes, there is a detectable change in abundance and/or one of the currencies from begin to end.

For  $\text{round}(100 \times \text{mean}(\text{grepl}(\text{"full"}, \text{actual\_winners}[\text{ which}(\text{actual\_winners}\$currency == \text{"energy"}), ]\$model)))$  percent (for energy) and  $\text{round}(100 \times \text{mean}(\text{grepl}(\text{"full"}, \text{actual\_winners}[\text{ which}(\text{actual\_winners}\$currency == \text{"biomass"}), ]\$model)))$  percent (for biomass) of routes, there is a *decoupling* of the dynamics of the currency from what would be expected given change in abundance alone.

### Direction of change in abundance

For about 70% of models *with an abundance slope that does not include 0*, abundance is decreasing.

### Direction of offset due to ISD

For models with a currency offset, nearly **80% of the time** that offset is towards the currency-slope being less negative than for abundance.

### Figure 1. Changes in biomass and energy use due to changes in the ISD vs. just abundance.

*Axes:* The x-axis is the change in the currency (energy use, top, or biomass, bottom) expected due only to change in abundance (as the mean for 2014:2018 divided by the mean for 1988:1992). The y-axis is the change in energy use/biomass taking into account change in the ISD. The sloped line marks the 1:1 line, which corresponds to change incorporating the ISD mirroring change due just to abundance. The crossbars mark 1, which corresponds to the beginning and the ending values being the same. The points are colored as follows: Blue means there is no slope term (intercept-only). Red means there is a change in abundance, but no difference in slopes between abundance and the currency (i.e. incorporating the ISD). Green means there is a decoupling.

*Interpretation:*

- There is a concentration towards decreases
- There is good correspondence to the 1:1 line. To a point.
- Jitter off the 1:1 line is concentrated above it, meaning the ISD is resulting in a less negative change over time. This is most pronounced for biomass.
- These plots give a sense of the magnitude of change that you can't get from summary tables, etc.

## Relating change in the ISD to decoupling

This figure shows the density distributions of overlap values for routes that are best-characterized using the different models (color scale). They don't really differ (p values > .8 for both energy and biomass).

**Figure 2. Change in the ISD vs. change in mean size.** *Axes:* The x axis is the ISD overlap for a route (ranges 0-1, with 1 being identical ISDs), and the y axis is the absolute log ratio of mean body size for the end vs the beginning. The points are individual routes; the line is the prediction from a quadratic model fitting `absolute_log_ratio ~ isd_overlap`.

*Interpretation:* The relationship between overall change in the ISD (overlap) and change *in mean body size* is a very messy one;  $R^2 = .06$ . It's not possible to have a *lot* of change in mean body size if there is very high ISD overlap, hence the slight negative relationship. However, for any given amount of change in the ISD there is a lot of variability in the effect on mean size.

## Core-transient

### Model tally comparison:

Restricting to just core species, we see fewer instances of decoupling, mostly for biomass.

Looking at the direction of change, first here is for all species for comparison:

And here is for core:

The skew towards decreases in abundance is slightly more pronounced for core than for “all” species.

Looking at the currency offsets, again here is “all species” for comparison:

And just for core:

**Restricted to core species, the decoupling is balanced above and below abundance.** It is changes in transient (and “intermediate”) species’ effects on the size structure that drive the skew towards increases in body size producing less-negative slopes for energy/biomass than what would happen just because of abundance.

# Discussion

## Results interpretation

1. While changes in size-based currencies usually scale with abundance, in a substantial minority of instances they do not. Meaning, there has been directional shift in the size structure that changes the outcome for function vs abundance.
  1. This means we should extrapolate from “abundance” to “function” with some care.
  2. And when these strong size shifts occur, it is also a prompt to dig deeper into what’s going on in that system.
2. When they diverge, it is usually in the direction of less-negative-change. Because abundance is usually decreasing, this is generally partially offsetting the decline in energy use/biomass that would be expected just given abundance.
  1. This contrasts with general in-the-ether concerns about size-biased declines disproportionately affecting large species. However, the increase in body size is consistent with other observations specific to BBS, possibly reflecting forests in recovery across North America.
  2. This skew towards an increase-in-size appears to be driven by the contributions of transient and intermediate species. Transients may be tracking different environmental cues than core species.
3. An absence of decoupling does not imply an absence of change in the ISD. Systems without a decoupling do not have more static ISDs than systems with a decoupling - it’s just that the change is not strongly skewed towards an increase or decrease.

## Considerations beyond the scope

1. Diagnosing process
  1. Attributing change in the size structure to species’ dynamics
    1. Why do the results for core v. all species differ?
    2. Is it the same species continent-wide accounting for shifts or does it vary geographically?
    3. Do shifts in the size structure map onto changes in land use? ETC.
  2. Disentangling process-driven shifts from drift.
    1. Null models at this scale are severely constrained in what they can tell us.
      1. A lot of the dynamics of change are baked into population sizes. There is not support to fit a neutral population dynamics model for BBS, so we have to take them as face-value constraints on dynamics. These strongly constrain the null models and limit the scope of what we can test using a null model.
      2. Highly-constrained null models for distinguishing process-driven vs drift in functional vs. taxonomic turnover tend to have a high type II error rate. When I have tested for ISDs, you need to have “pure” change (all the change in the ISD is towards an increase in body size, or all the change in the ISD is like-for-like size structured replacement) in order to deviate from the null model.
    2. That said, I don’t generally find deviations from null models in these results (although I am not sure because the computational requirements are too great to run this very many times).
    3. Rather than trying to distinguish process-driven from random change at the continental scale, I therefore suggest using these dynamics to guide more focused investigations at the route level.
2. Extrapolating beyond BBS
  1. BBS routes may not be representative of biodiversity change for other taxa or (especially) globally
3. The current method cannot account for **intraspecific** size variation over time or space, which may be important.

## Wider significance

1. The interrelated dynamics of the size structure, total abundance, and community function have a rich history in aquatic and tree systems. This study is a first step towards translating this approach to terrestrial animal systems.
2. We show that terrestrial animal ISDs change over time, and that these changes can have significant cascading effects on the scaling between abundance and size-based measures of function.
3. Incorporating the ISD is important to fully characterize biodiversity change, especially in the Anthropocene.
4. Our study provides the motivation and a quantitative approach for studying these dynamics, which can be applied either in greater depth (to understand the processes driving change in specific communities) or in novel taxonomic or geographic contexts (e.g. mammals, birds beyond BBS).
5. We hope that this can launch a new chapter of research on the size spectrum and its relation to community function in terrestrial systems.
